(Dated: 20 November 2012)

For a random walk on a network, the mean first-passage time from a node i to another node j chosen stochastically according to the equilibrium distribution of Markov chain representing the random walk is called Kemeny constant, which is closely related to the navigability on the network. Thus, the configuration of a network that provides optimal or suboptimal navigation efficiency is a question of interest. It has been proved that complete graphs have the exact minimum Kemeny constant over all graphs. In this paper, by using another method we first prove that complete graphs are the optimal networks with a minimum Kemeny constant, which grows linearly with the network size. Then, we study the Kemeny constant of a class of sparse networks that exhibit remarkable scale-free and fractal features as observed in many real-life networks, which cannot be described by complete graphs. To this end, we determine the closed-form solutions to all eigenvalues and their degeneracies of the networks. Employing these eigenvalues, we derive the exact solution to the Kemeny constant, which also behaves linearly with the network size for some particular cases of networks. We further use the eigenvalue spectra to determine the number of spanning trees in the networks under consideration, which is in complete agreement with previously reported results. Our work demonstrates that scale-free and fractal properties are favorable for efficient navigation, which could be considered when designing networks with high navigation efficiency.

Keywords: Random walks, Mean first-passage time, Complex networks, Scale-free networks

Kemeny constant, defined as the mean first-passage time from a node i to a node j selected randomly according to the equilibrium distribution of Markov chain, is a fundamental quantity for a random walk, since it is a useful indicator characterizing the efficiency of navigation on networks. Here we prove that among all networks, complete graph is the optimal network having the least Kemeny constant, which is consistent with the previous result obtained by a different method. Then, we study the Kemeny constant of a class of sparse scale-free fractal networks, which are ubiquitous in real-life systems. By using the renormalization group technique, we derive the explicit formulas for all eigenvalues and their multiplicities of the networks, based on which we determine the closed-form solution to the Kemeny constant. We show that for some particular cases of networks the leading scaling of Kemeny constant displays the same behavior as that of complete graph, indicating that for networks with many nodes, navigation performance similar to that of complete graph can be obtained by networks with many few links. Finally, to show the validity of the eigenvalues and their degeneracies, we also use them to count spanning trees in the networks being studied, and recover previously reported results. Our work is helpful for the structure design of networks where navigation is very efficient.

I. INTRODUCTION

In the past decade, many research reports demonstrated that complex networks are ubiquitously present in nature and social sciences[1–3]. Today, complex networks have been recognized as an emerging subject and useful tool for studying complex systems[4]. An outstanding issue in network science is to understand the behavior of various dynamical and stochastic processes taking place on different networks with rich topologies, which is not only of theoretical interest but also of practical relevance[2,5]. Among diverse dynamics, random walks[6–8] are a paradigmatic process and have been extensively stud-

ied[9–17] due to their wide range of applications in science and engineering[18–21].

A fundamental quantity for random walks is mean first-passage time (MFPT)[22]. The MFPT from a source node i to a destination node j, denoted by F_{ij}, is the expected time for a walker starting from i to reach j for the first time. Many other quantities related to random walks can be expressed in terms of, or encoded in, MFPT. For example, for the trapping problem[23]—a particular case of random walks with a trap located at a given node absorbing walkers visiting it—the trapping efficiency quantified by average trapping time is defined as the mean of node-to-trap MFPT over source nodes. As a quantitative indicator of trapping efficiency, average trapping time has been studied on various networks with distinct topological properties, with an attempt to uncover the impact of network topology on the trapping process. Examples include classic fractals[24–29], non-fractal scale-free networks[30–35], fractal scale-free networks[36–38], modular scale-free networks[39,40], and so on.

In addition to the trapping problem, another interesting quantity derived from MFPT is the Kemeny constant, which is defined as the expected time for a walker starting from a node i to another node j selected randomly from all nodes according to the stationary distribution of Markov chain representing the random walk[41]. Since the Kemeny constant is equal to the sum of reciprocals of one minus each eigenvalue of the transition matrix other than eigenvalue one[42], it is also called eigentime identity[43], which is independent of the starting point. It can be explained in terms of navigability[44], measuring the efficiency of navigation. Thus, it is of theoretical and practical significance to study the Kemeny constant of complex networks. In contrast to the average trapping time, little attention has been paid to the Kemeny constant, and many questions about this relevant quantity are still open.

In this paper, we address a specific question: of all networks, which have a minimum or almost minimum Kemeny constant? It is of theoretical relevance and practical importance, and is particularly useful for network design. By making use of the connection between the Kemeny constant and eigenvalues of the transition matrix, we first show that among all undirected networks complete graphs have the minimum Kemeny constant growing linearly with the network size, which agrees with result reported before[43]. However, since most real networks are spare in the sense that their average degrees are much less than that of complete graphs. Moreover, it was shown that many real networks exhibit the striking scale-free[45] and fractal[46] properties. Here we study the Kemeny constant for a class of sparse scale-free fractal networks[47], denoted by $H(q,n)$, which are parameterized by a positive integer $q \geq 2$. Using the decimation technique, we derive explicit expressions for all eigenvalues and their multiplicities of the transition matrix of $H(q,n)$, based on which we derive a closed-form formula for the Kemeny constant. The obtained result shows that, for $q \geq 3$, the Kemeny constant also scales linearly with the network size, displaying the same scaling as that of complete graphs. Finally, we use the eigenvalues of $H(q,n)$ to determine the number of spanning trees and recover previous results, which also validates our computation of eigenvalues for such networks.

II. FORMULATION OF THE PROBLEM

Consider discrete-time unbiased random walks[6] on a connected undirected network G with N nodes and E edges, where the N nodes are labeled by $1, 2, 3, \ldots, N$, respectively. The connectivity of G is encoded in its adjacency matrix A, whose entry $a_{ij} = 1$ (or 0) if nodes i and j are (not) connected by an edge. The degree of node i is defined to be $d_i = \sum_{j=1}^{N} a_{ij}$, and the diagonal degree matrix of G, denoted by D, is defined as: the ith diagonal element is d_i, while all non-diagonal elements are zero. Thus, the total degree of all nodes is $K = 2E = \sum_{j=1}^{N} d_i$, and the average degree is $\langle d \rangle = 2E/N$.

For the unbiased random walks considered here, at every time step the walker starting from its current location jumps to each of its neighbors with an identical probability. Such a stochastic process is characterized by the transition matrix $T = D^{-1}A$, whose entry $t_{ij} = a_{ij}/d_i$ presents the probability of moving from i to j in one step. Note that the transition matrix is also called the Markov matrix, since a random walk is an ergodic Markov chain[41,43], whose stationary distribution $\pi = (\pi_1, \pi_2, \ldots, \pi_N)^\top$ is a unique probabilistic vector satisfying $\pi_i = d_i/K$, $\sum_{i=1}^{N} \pi_i = 1$, and $\pi^\top T = \pi^\top$.

In general, the transition matrix T is asymmetric except for regular networks. So, we introduce a matrix P similar to T by

$$P = D^{-\frac{1}{2}} A D^{-\frac{1}{2}} = D^{\frac{1}{2}} T D^{-\frac{1}{2}}, \tag{1}$$

where $D^{-\frac{1}{2}}$ is defined as follows[48]: the ith diagonal entry is $1/\sqrt{d_i}$, while all non-diagonal entries are equal to zero. It is evident that P is real and symmetrical and thus has the same eigenvalues as T.

Various interesting quantities related to random walks are encoded in matrix P, and thus can be deduced from P. For example, the MFPT F_{ij} for a walker starting from a node i to another node j can be expressed in terms of the eigenvalues and their orthonormalized eigenvectors of matrix P. Let λ_1, λ_2, λ_3, …, λ_N be the N (real) eigenvalues of matrix P, rearranged as $1 = \lambda_1 > \lambda_2 \geq \lambda_3 \geq \cdots \geq \lambda_N \geq -1$. Obviously, $\lambda_1 + \lambda_2 + \lambda_3 + \cdots + \lambda_N = 0$. And let ψ_1, ψ_2, ψ_3, …, ψ_N denote the corresponding normalized, real-valued and mutually orthogonal eigenvectors, where $\psi_i = (\psi_{i1}, \psi_{i2}, \ldots, \psi_{iN})^\top$. Then,

$$F_{ij} = \frac{K}{d_j} \sum_{k=2}^{N} \frac{1}{1-\lambda_k} \left(\psi_{kj}^2 - \psi_{ki}\psi_{kj} \sqrt{\frac{d_j}{d_i}} \right), \tag{2}$$

which has been derived by various methods, e.g., generating functions[8] and spectral graph theory[42].

Another interesting quantity for random walks is the Kemeny constant[41], also referred to as eigentime identity[43], defined by

$$F = \sum_{j=1}^{N} \pi_j \, F_{ij} \, . \tag{3}$$

Equation (4) indicates that F is the average of MFPT F_{ij} from node i to node j randomly chosen from all nodes accordingly to the stationary distribution. Since F is independent of the starting point i, it is thus called the Kemeny constant. This quantity is closely related to user navigation through World Wide Web and can be explained as the mean number of edges the random surfer needs to follow before reaching his/her final destination[44].

Note that the Kemeny constant is a global spectral characteristic of a network[8,41,43]. It has been shown[8,41,43] that

$$F = \sum_{j=1}^{N} \pi_j \, F_{ij} \equiv \sum_{k=2}^{N} \frac{1}{1-\lambda_k} \, , \tag{4}$$

which holds for any connected undirected network. Kemeny constant can be used as a measure of navigation efficiency[44] and is thus relevant to Web design: small F can save user's effort by directly guiding them to most desirable Web pages. Since F depends on the network structure, a question arises naturally: what is the optimal network structure that has a minimum Kemeny constant? Intuitively, the globally optimal network should be fully connected. In the sequel, we will address this question analytically by using the spectra of graphs and method of Lagrange multipliers, and show that the eigenvalue treatment arrives at the intuitive and natural conclusion.

III. GLOBALLY OPTIMAL NETWORK

We now solve the aforementioned problem by using the method of Lagrange multipliers. We consider the following function:

$$f(x_2, \cdots, x_N) = \sum_{k=2}^{N} \frac{1}{1-x_k} \, , \tag{5}$$

subject to the condition of $1 + x_2 + \cdots + x_N = 0$ on the domain $1 > x_2 \geq x_3 \geq \cdots \geq x_N \geq -1$. Applying the method of Lagrange multipliers to Eq. (5), the minimum of the function $f(x_2, \cdots, x_N)$ is attained at $x_2 = x_3 = \cdots = x_N = -1/(N-1)$. Thus, the minimum Kemeny constant among all networks of size N is

$$F_{\min} = \frac{(N-1)^2}{N} \, . \tag{6}$$

As one can see, the above set of identical eigenvalues $\lambda_2 = \lambda_3 = \ldots = \lambda_N = -1/(N-1)$ corresponds to those of the transition matrix of a complete graph with N nodes, in which every node is connected to all others. That is, among all connected undirected networks, complete network is optimal in the sense that it has the absolute minimum Kemeny constant, which can not be achieved by other networks. We note Eq. (6) has been previously proved by using a different approach[43]. It is obvious from Eq. (6) that for large N, $F_{\min}$ scales linearly with N.

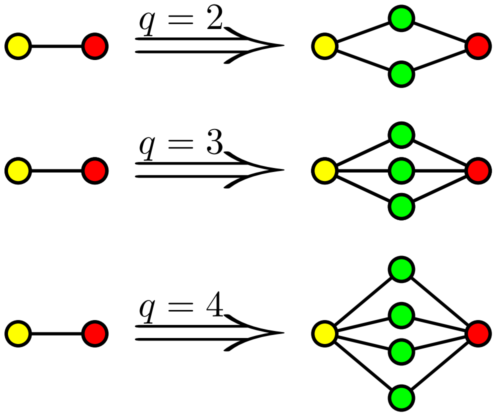

FIG. 1. (Color online) Construction of the networks. One can obtain the next generation of the network family through replacing each edge of the present generation by the clusters on the right-hand side of the arrows.

Although a complete network has the minimum Kemeny constant, it is dense, not like most real networks. Extensive empirical research has shown[1–3] that most real networks are sparse, which have a small average degree and display simultaneously scale-free[45] and fractal[46] properties. Below, we will study the Kemeny constant for a family of fractal scale-free sparse networks[47] parameterized by a positive integer $q \geq 2$. We will show that for those networks corresponding to $q \geq 3$, the dominating term of their Kemeny constant grows linearly with the network size N, which is similar to the linear behavior of complete graphs but with a different prefactor $\frac{q-1}{q-2}$ larger than 1. Thus, when $q \geq 3$, the networks are called "suboptimal networks".

IV. SUBOPTIMAL SCALE-FREE FRACTAL NETWORKS

In the section, we study random walks on a class of scale-free (heterogenous) fractal networks[47], the properties of which are dominated by an integer parameter $q \geq 2$.

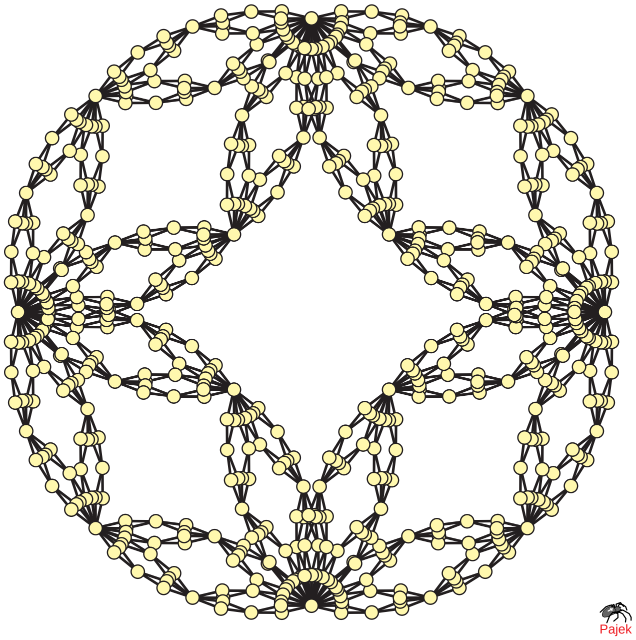

FIG. 2. (Color online) Illustration for the network $H(2,5)$.

A. Construction and properties

The scale-free fractal networks studied in[47] are constructed in an iterative manner as depicted by Fig. 1. Let $H(q,n)$ ($q \geq 2$ and $n \geq 0$) denote the networks after n iterations. Initially ($n=0$), $H(q,0)$ is an edge connecting two nodes. For $n \geq 1$, $H(q,n)$ is generated from $H(q,n-1)$ by replacing every existing edge in $H(q,n-1)$ with the clusters on the right-hand side of the arrows in Fig. 1. When $q=2$, $H(q,n)$ is reduced to the $(2,2)-$flower, which is a special case of the $(u,v)-$flowers ($u \geq 1$, $v \geq 2$) presented in[49,50]. Figure 2 illustrates the network $H(2,5)$ for the particular case of $q=2$, which is called diamond lattice and was introduced more than thirty years ago[51].

The iterative construction allows to precisely analyze relevant properties of the networks. At each generation n_i ($n_i \geq 1$), the number of newly introduced nodes is $V_{n_i} = q(2q)^{n_i-1}$. Then, the network size (number of nodes) N_n of $H(q,n)$ is

$$N_n = \sum_{n_i=0}^{n} V_{n_i} = \frac{q(2q)^n + 3q - 2}{2q-1}\,. \tag{7}$$

Let E_n denote the number of total edges in $H(q,n)$. It is easy to verify that

$$E_n = qE_{n-1} = (2q)^n\,. \tag{8}$$

Let $d_i(n)$ be the degree of node i in $H(q,n)$ that was generated at iteration n_i ($n_i \geq 1$). Then, we have $d_i(n+1) = q\,d_i(n) = 2\,q^{n-n_i}$.

These resultant networks display some remarkable features observed in various real-life systems. They have a power-law degree distribution with exponent $\gamma = 2 + \ln 2/\ln q$, and have a fractal dimension $f_{\mathrm{B}} = \ln(2q)/\ln 2$, both of which show that they are fractal scale-free networks[47,49,50]. Moreover, they are "large-world", with both of their diameter and average distance increasing as a power function of the network size[47,49,50]. We note that this "large-world" phenomenon was also observed in the global network of avian influenza outbreaks[52,53].

B. Spectrum of the transition matrix

After introducing the construction method and properties of the networks, we proceed to determine the eigenvalues and their degeneracies of the transition matrix for the network family, which will be useful for evaluating the Kemeny constant.

1. Eigenvalue spectrum

Let A_n and D_n denote, respectively, the adjacency matrix and diagonal degree matrix of $H(q,n)$. The entry $A_n(i,j)$ of A_n is defined as: $A_n(i,j)=1$ if nodes i and j are directly connected in $H(q,n)$, $A_n(i,j)=0$ otherwise. Then, the transition matrix of $H(q,n)$, denoted by T_n, is defined as $T_n = (D_n)^{-1}A_n$. Thus, the entry of T_n is $T_n(i,j) = A_n(i,j)/d_i(n)$.

We now begin to compute the eigenvalues of T_n. Since T_n is asymmetric, we introduce a real symmetric matrix P_n similar to T_n by

$$P_n = (D_n)^{-\frac{1}{2}} A_n (D_n)^{-\frac{1}{2}} = (D_n)^{\frac{1}{2}} T_n (D_n)^{-\frac{1}{2}}. \tag{9}$$

Thus, we reduce the problem of determining eigenvalues of T_n to calculating those of P_n, with entries $P_n(i,j) = \frac{A_n(i,j)}{\sqrt{d_i(n)}\sqrt{d_j(n)}}$.

Next, we apply the decimation method[54–57] to compute the eigenvalues and their multiplicities of P_n. Let us consider the eigenvalues of matrix P_{n+1}. For this purpose, we use α to denote the set of nodes belonging to $H(q,n)$, and β the set of nodes created at iteration $n+1$. By definition, P_{n+1} has the following block form:

$$P_{n+1} = \begin{bmatrix} P_{\alpha,\alpha} & P_{\alpha,\beta} \\ P_{\beta,\alpha} & P_{\beta,\beta} \end{bmatrix} = \begin{bmatrix} 0 & P_{\alpha,\beta} \\ P_{\beta,\alpha} & 0 \end{bmatrix}, \tag{10}$$

where we have used the fact that $P_{\alpha,\alpha}$ and $P_{\beta,\beta}$ are two zero matrices with orders being $N_n \times N_n$ and $(N_{n+1} - N_n) \times (N_{n+1} - N_n)$, respectively. The reason for $P_{\alpha,\alpha}$ and $P_{\beta,\beta}$ being zero matrices lies in the iterations and insertion constraint in the construction process of networks, as shown in Fig. 1.

Suppose $\lambda_i(n+1)$ is an eigenvalue of P_{n+1}, and $u = (u_\alpha, u_\beta)^\top$ is its associated eigenvector, where u_α and u_β correspond to nodes in α and β, respectively. Then, the eigenvalue equation for matrix P_{n+1} has the following block form:

$$\begin{bmatrix} 0 & P_{\alpha,\beta} \\ P_{\beta,\alpha} & 0 \end{bmatrix} \begin{bmatrix} u_\alpha \\ u_\beta \end{bmatrix} = \lambda_i(n+1) \begin{bmatrix} u_\alpha \\ u_\beta \end{bmatrix}, \tag{11}$$

which can be rewritten as

$$P_{\alpha,\beta} u_\beta = \lambda_i(n+1) u_\alpha, \tag{12}$$

$$P_{\beta,\alpha} u_\alpha = \lambda_i(n+1) u_\beta. \tag{13}$$

In the case of $\lambda_i(n+1) \neq 0$, Eq. (13) gives rise to

$$u_\beta = \frac{1}{\lambda_i(n+1)} P_{\beta,\alpha} u_\alpha\,. \tag{14}$$

Inserting Eq. (14) into Eq. (12) yields

$$\frac{1}{\lambda_i(n+1)} P_{\alpha,\beta} P_{\beta,\alpha} u_\alpha = \lambda_i(n+1) u_\alpha. \tag{15}$$

Thus, the problem of determining the eigenvalues for matrix P_{n+1} of order $N_{n+1} \times N_{n+1}$ is reduced to calculating the eigenvalues of matrix $P_{\alpha,\beta}P_{\beta,\alpha}$ with a smaller order of $N_n \times N_n$.

In Appendix A, we prove that

$$P_{\alpha,\beta}P_{\beta,\alpha} = \frac{1}{2} I_n + \frac{1}{2} P_n, \tag{16}$$

where I_n is the identity matrix of order $N_n \times N_n$, same as that of P_n. Thus, we have related $P_{\alpha,\beta}P_{\beta,\alpha}$ to P_n, which allows to express the eigenvalues of matrix P_{n+1} in terms of those of P_n.

Plugging Eq. (16) into Eq. (15) gives

$$\frac{1}{\lambda_i(n+1)} \left(\frac{1}{2} I_n + \frac{1}{2} P_n \right) u_\alpha = \lambda_i(n+1) u_\alpha, \tag{17}$$

that is,

$$P_n u_\alpha = \left\{ 2[\lambda_i(n+1)]^2 - 1 \right\} u_\alpha. \tag{18}$$

Hence, if $\lambda_i(n)$ is an eigenvalue of P_n corresponding to the eigenvector u_α, then Eq. (18) implies

$$\lambda_i(n) = 2[\lambda_i(n+1)]^2 - 1. \tag{19}$$

Solving the quadratic equation (19) in variable $\lambda_i(n+1)$ gives two roots:

$$\lambda_{i,1}(n+1) = \sqrt{\frac{\lambda_i(n)+1}{2}}, \quad \lambda_{i,2}(n+1) = -\sqrt{\frac{\lambda_i(n)+1}{2}}, \tag{20}$$

which relate $\lambda_i(n+1)$ to $\lambda_i(n)$, with each $\lambda_i(n)$ producing two eigenvalues of P_{n+1}.

2. Multiplicities of eigenvalues

To determine the multiplicities of eigenvalues, we first calculate numerically the eigenvalues for those networks of small sizes. For $n = 0$, the eigenvalues of P_0 are 1 and -1; while for $n = 1$, the eigenvalues of matrix P_1 corresponding to $H_{q,1}$ are 1, -1, and 0 with multiplicity q. For $n \geq 2$, we find that the eigenvalue spectrum displays the following properties: (i) Eigenvalues 1 and -1 are present at all generations, both having a single degeneracy. (ii) All eigenvalues of generation n_i will always exist at its subsequent generation $n_i + 1$, and all new eigenvalues at generation $n_i + 1$ are just those generated via Eq. (20) by substituting $\lambda_i(n)$ with $\lambda_i(n_i)$ that are newly added to generation n_i; moreover, each new eigenvalue keeps the degeneracy of its father. (iii) Except for 1 and -1, all other eigenvalues are derived from generated 0. Thus, all that is left to determine are the degeneracy of 0 and the multiplicities of its offsprings, based on property (ii).

Let $D_n^{\rm mul}(\lambda)$ denote the multiplicity of eigenvalue λ of matrix P_n. We now find the number of eigenvalue 0 of P_n. Let $r(M)$ denote the rank of matrix M. Then, the degeneracy of eigenvalue 0 of P_{n+1} is

$$D_{n+1}^{\rm mul}(\lambda = 0) = N_{n+1} - r(P_{n+1})\,. \tag{21}$$

In Appendix B, we derive the exact expression for the degeneracy of eigenvalue 0 of P_n as

$$D_n^{\rm mul}(\lambda = 0) = \begin{cases} 0, & n = 0, \\ \frac{(q-1)(2q)^n + q}{2q-1}, & n \geq 1. \end{cases} \tag{22}$$

Since every eigenvalue in P_n keeps the degeneracy of its father, the multiplicity of each first-generation descendants of eigenvalue 0 is $\frac{(q-1)(2q)^{n-1}+q}{2q-1}$, the multiplicity of each second-generation descendants of eigenvalue 0 is $\frac{(q-1)(2q)^{n-2}+q}{2q-1}$, and so on. Thus, for P_n ($n \geq 1$), the total number of eigenvalue 0 and all of its descendants is

$$\begin{aligned} N_n^{\rm seed}(0) &= \sum_{i=1}^{n} \left[\frac{(q-1)(2q)^i + q}{2q-1} \times 2^{n-i} \right] \\ &= \frac{q(2q)^n - q}{2q-1}. \end{aligned} \tag{23}$$

Summing up the multiplicities of eigenvalues obtained above, we have

$$N_n^{\rm seed}(0) + D_n^{\rm mul}(-1) + D_n^{\rm mul}(1) = \frac{q(2q)^n + 3q - 2}{2q-1} = N_n. \tag{24}$$

Thus, we have found all the eigenvalues of P_n.

Thus far, we have given a recursive expression for eigenvalues of the transition matrix for $H(q,n)$, as well as the multiplicity of each eigenvalue. In fact, for the special network family $H(q,n)$ considered here, their eigenvalues can be expressed in an explicit way, as shown in Appendix C. These exact expressions contain more concrete information about eigenvalues than that of the recursive relation provided by Eq. (20).

C. The Kemeny constant

We proceed to use the obtained eigenvalues and their multiplicities to determine the Kemeny constant for the fractal scale-free networks $H(q,n)$.

Let $F_{ij}(n)$ denote the MFPT from node i to node j in $H(q,n)$. Let $\pi = (\pi_1, \pi_2, \ldots, \pi_{N_n})^\top$ represent the stationary distribution[42,43] for random walks on $H(q,n)$. It is easy to verify that $\pi_i = d_i(n)/(2E_n)$. Then, the Kemeny constant for $H(q,n)$, denoted by F_n, is given by

$$F_n = \sum_{j=1}^{N_n} \pi_j \, F_{ij}(n) = \sum_{i=2}^{N_n} \frac{1}{1-\lambda_i(n)}, \tag{25}$$

where we have assumed that $\lambda_1(n) = 1$.

Let L_n be the normalized Laplacian matrix[48,58] of $H(q,n)$, defined as $L_n = I_n - P_n = I_n - (D_n)^{\frac{1}{2}} T_n (D_n)^{-\frac{1}{2}}$. Let σ_1, σ_2, σ_3, $\cdots$, σ_{N_n} be the N_n real non-negative eigenvalues of matrix L_n, rearranged as $0 = \sigma_1 < \sigma_2 \leq \sigma_3 \leq \ldots \leq \sigma_{N_n} = 2$. Note that for any i, $\sigma_i(n) = 1 - \lambda_i(n)$. Then,

$$F_n = \sum_{i=2}^{N_n} \frac{1}{\sigma_i(n)}. \tag{26}$$

Next, we explicitly evaluate this sum.

Let Ω_n be the set of all the $N_n - 1$ nonzero eigenvalues of matrix L_n, i.e., $\Omega_n = \{\sigma_2(n), \sigma_3(n), \ldots, \sigma_{N_n}(n)\}$, in which the distinction of the elements has been ignored. It is clear that Ω_n ($n \geq 1$) includes 1, 2, and other eigenvalues generated by 1. Then, Ω_n can be classified into three subsets represented by $\Omega_n^{(1)}$, $\Omega_n^{(2)}$ and $\Omega_n^{(3)}$, respectively. That is, $\Omega_n = \Omega_n^{(1)} \cup \Omega_n^{(2)} \cup \Omega_n^{(3)}$, where $\Omega_n^{(1)}$ consists of eigenvalue 1 with multiplicity $\frac{(q-1)(2q)^n+q}{2q-1}$, $\Omega_n^{(2)}$ contains only eigenvalue 2 with single degeneracy, and $\Omega_n^{(3)}$ includes those eigenvalues generated by 1. Obviously, $\sum_{\sigma_i(n)\in\Omega_n^{(1)}} \frac{1}{\sigma_i(n)} = \frac{(q-1)(2q)^n+q}{2q-1}$ and $\sum_{\sigma_i(n)\in\Omega_n^{(2)}} \frac{1}{\sigma_i(n)} = \frac{1}{2}$.

For each eigenvalue $\sigma_i(n-1)$ in $\Omega_{n-1}^{(3)}$, it generates two eigenvalues, $\sigma_{i,1}(n)$ and $\sigma_{i,2}(n)$, belonging to $\Omega_n^{(3)}$, via the following equation:

$$2[\sigma_i(n)]^2 - 4\sigma_i(n) + \sigma_i(n-1) = 0\,, \tag{27}$$

which can be easily obtained from Eq. (19). According to Vieta's formulas, we have

$$\sigma_{i,1}(n) + \sigma_{i,2}(n) = 2 \tag{28}$$

and

$$\sigma_{i,1}(n) \times \sigma_{i,2}(n) = \frac{\sigma_i(n-1)}{2}\,. \tag{29}$$

Then

$$\frac{1}{\sigma_{i,1}(n)} + \frac{1}{\sigma_{i,1}(n)} = \frac{4}{\sigma_i(n-1)}, \tag{30}$$

which indicates that

$$\begin{aligned} \sum_{\sigma_i(n)\in\Omega_n^{(3)}} \frac{1}{\sigma_i(n)} &= 4 \sum_{\substack{\sigma_i(n-1)\in\Omega_{n-1} \\ \sigma_i(n-1)\neq 2}} \frac{1}{\sigma_i(n-1)} \\ &= 4\left(F_{n-1} - \frac{1}{2}\right). \end{aligned} \tag{31}$$

Thus, we have

$$F_n = 4\,F_{n-1} + \frac{(q-1)(2q)^n+q}{2q-1} - \frac{3}{2}. \tag{32}$$

Considering the initial condition $F_0 = \frac{1}{2}$, Eq. (32) can be solved by distinguishing two cases: $q = 2$ and $q \geq 3$. For $q = 2$,

$$F_n = \frac{1}{18}\left(6n \times 4^n + 4^{n+1} + 5\right)\,; \tag{33}$$

while for $q \geq 3$,

$$F_n = \frac{3(q-1)(2q)^{n+1} - 2q(2q-1)4^n + 4q^2 - 11q + 6}{6(q-2)(2q-1)}\,. \tag{34}$$

We now express F_n as a function of the network size N_n. For the case of $q = 2$, we have $4^n = \frac{3}{2}N_n - 2$ and $n = \log_4\left(\frac{3}{2}N_n - 2\right)$, which can be easily obtained from Eq. (7). Thus, Eq. (33) can be rewritten in terms of N_n as

$$F_n = \left(\frac{1}{2}N_n - \frac{2}{3}\right)\log_4\left(\frac{3}{2}N_n - 2\right) + 6N_n - 3\,. \tag{35}$$

Similarly to the case of $q = 2$, for $q \geq 3$ we can derive that $(2q)^n = \frac{(2q-1)N_n - 3q + 2}{q}$ and $4^n = \left[\frac{(2q-1)N_n-3q+2}{q}\right]^{\log_{2q} 4}$. Inserting these relations into Eq. (34) leads to

$$\begin{aligned} F_n = {}& \frac{q-1}{q-2}N_n + \frac{22q^2 - 41q + 18}{6(q-2)(2q-1)} \\ & - \frac{q}{3(q-2)}\left[\frac{(2q-1)N_n - 3q + 2}{q}\right]^{\log_{2q} 4}\,. \end{aligned} \tag{36}$$

Equations (35) and (36) show that, for large networks, i.e., $N_g \to \infty$, the leading terms in the Kemeny constant for $H(q,n)$ follow distinct scalings for the two cases of $q = 2$ and $q \geq 3$. For the former case,

$$F_n \sim N_n \ln N_n\,; \tag{37}$$

while for the latter case,

$$F_n \sim N_n\,. \tag{38}$$

It should be stressed that, for $q \geq 3$, the linear growth of the Kemeny constant for sparse $H(q,n)$ is similar to that for dense complete graphs. In this sense, we say that the scale-free fractal networks $H(q,n)$ (for $q \geq 3$) are suboptimal networks.

Finally, we note that the validity of the above-obtained results for the Kemeny constant depends on that of the eigenvalues. In Appendix D, to verify that our computation on the eigenvalues of the transition matrix is correct, we compute the number of spanning trees in $H(q,n)$ using the connection between spanning trees and the eigenvalues of the normalized Laplacian matrix, which reproduces previously obtained results for the number of spanning trees in $H(q,n)$[59]. This indeed validates our computations.

V. CONCLUSIONS

To conclude, by applying a different method from before, we have shown that among all networks, complete graphs are optimal in the sense that they have the minimum Kemeny constant, which scales linearly with the network size. However, due to the limitations of cost and other factors, complete graphs are not typical in the real world, where most systems are described by sparse networks displaying simultaneously scale-free and fractal properties. To explore networks having such properties of real systems but with a small Kemeny constant, we have also studied random walks on a scale-free fractal network family, characterized by a positive integer parameter. We have derived explicit formulas for all eigenvalues and their multiplicities of the transition matrix for such networks. Using these results, we have further determined the eigentime identity, which also displays a linear growth with the network size as complete graphs. At last, to test our results on the spectra of the transition matrix for the scale-free fractal networks, we have computed the number of their spanning trees, which is consistent with those previously obtained results by means of a different method. Our work may have important implications on the design of complex networks with efficient navigation.

Appendix A: Proof of equation (16)

In order to prove $P_{\alpha,\beta}P_{\beta,\alpha} = \frac{1}{2}I_n + \frac{1}{2}P_n$, it suffices to show that their corresponding entries are equal to each other. For simplicity, let $Q_n = \frac{1}{2}I_n + \frac{1}{2}P_n$, the entries of which are: $Q_n(i,i) = \frac{1}{2}$ for $i = j$ and $Q_n(i,j) = \frac{1}{2}P_n(i,j)$ otherwise. Let $R_n = P_{\alpha,\beta}P_{\beta,\alpha}$, whose entries $R_n(i,j)$ can be determined as follows. Note that $P_{\alpha,\beta}$ can be written as

$$P_{\alpha,\beta} = \begin{pmatrix} M_1^\top \\ M_2^\top \\ \vdots \\ M_{N_n}^\top \end{pmatrix}, \tag{A1}$$

where each M_i is a column vector of order $N_{n+1} - N_n$. Since $P_{\alpha,\beta} = P_{\beta,\alpha}^\top$, we have $P_{\beta,\alpha} = (M_1\ M_2\ \dots M_{N_n})$. Then, the entry $R_n(i,j) = M_i^\top M_j$ of R_n can be determined by distinguishes two cases, as follows.

If $i = j$, then the diagonal element of R_n is

$$\begin{aligned} R_n(i,i) &= M_i^\top M_i \\ &= \sum_{k\in\beta} P_{n+1}(i,k)P_{n+1}(k,i) \\ &= \sum_{k\in\beta} \frac{A_{n+1}(i,k)}{d_i(n+1)d_k(n+1)} \\ &= \frac{1}{d_i(n+1)} \sum_{k\in\beta,\, i\sim k} \frac{1}{2} \\ &= \frac{1}{2}, \end{aligned} \tag{A2}$$

where $i \sim k$ stands for that nodes i and k are adjacent in $H_{q,n+1}$ and the fact $d_k(n+1) = 2$ was used.

If $i \neq j$, the non-diagonal element of R_n is

$$\begin{aligned} & R_n(i,j) = M_i^\top M_j \\ &= \sum_{k\in\beta} P_{n+1}(i,k)P_{n+1}(k,j) \\ &= \sum_{\substack{A_{n+1}(i,k)=1 \\ A_{n+1}(k,j)=1}} \frac{A_n(i,j)}{d_k(n+1)\sqrt{d_i(n+1)d_j(n+1)}} \\ &= \frac{A_n(i,j)}{2\sqrt{d_i(n)d_j(n)}} = \frac{1}{2}P_n(i,j) = Q_n(i,j), \end{aligned} \tag{A3}$$

where the relations $d_i(n+1) = q\,d_i(n)$ and $d_j(n+1) = q\,d_j(n)$ have been used. Thus, Eq. (16) is proved.

Appendix B: Derivation of equation (22)

Equation (21) shows that in order to determine $D_{n+1}^{\mathrm{mul}}(\lambda = 0)$, we can alternatively compute $r(P_{n+1})$. Obviously, $r(P_{n+1}) = r(P_{\alpha,\beta}) + r(P_{\beta,\alpha}) = 2r(P_{\beta,\alpha})$, where $r(P_{\alpha,\beta}) = r(P_{\beta,\alpha})$ is used.

We next determine $r(P_{\beta,\alpha})$. As defined in Appendix A, $P_{\beta,\alpha} = (M_1\ M_2\ \cdots M_{N_n})$, where $M_i = (M_{1,i}, M_{2,i}, \cdots, M_{N_{n+1}-N_n,i})^\top$. We first show that M_1, M_2, …, and M_{N_n} are linearly dependent. To this end, we label one node in $H(q,0)$ by 1. Then, all nodes in $H(q,n+1)$ can be categorized into $2^{n+1}+1$ classes C_i ($i = 0, 1, \dots, 2^{n+1}$), according to the shortest distance between any of them and node 1. Let $d(x,y)$ denote the shortest distance from node x to node y

in $H(q, n+1)$, and C_i be the set of nodes defined by $C_i = \{u|d(1,u) = i\}$. Then, the set α of old nodes belonging to $H(q, n+1)$ is $\alpha = \bigcup\limits_{i=0}^{2^n} C_{2i}$, and set β of new nodes born at generation $n+1$ is $\beta = \bigcup\limits_{i=1}^{2^n-1} C_{2i-1}$. It is not difficult to verify that

$$\sum_{\substack{u=1\\u\in\alpha}}^{N_n} \left[(-1)^{d(1,u)/2} M_u\right] = 0. \tag{B1}$$

Therefore, column vectors M_1, M_2, …, and M_{N_n} are linearly dependent.

We next demonstrate that the $N_n - 1$ vectors M_2, M_3, …, and M_{N_n} are linearly independent. Let

$$v = (v_2, v_3, \dots, v_{N_{n+1}-N_n})^\top = \sum_{\substack{i=2\\i\in\alpha}}^{N_n} k_i M_i. \tag{B2}$$

Suppose that $v = 0$, and we will prove that for an arbitrary k_i, $k_i = 0$ always holds. Note that for a node $w \in \beta$, it has two neighbors, denoted by $w_{\rm pre}$ and $w_{\rm suc}$: $w_{\rm pre}$ is the neighbor near by node 1, while $w_{\rm suc}$ is the other neighbor farther from node 1. If $w \in C_1$, then $v_w = k_{w_{\rm pre}} + k_{w_{\rm suc}}$. Since, in this case, $k_{w_{\rm pre}}$ is just node 1, $v_w = 0$ leads to $k_{w_{\rm suc}} = 0$. Let's consider a node $j \in C_2$. By construction, there exists a node $w \in C_1$ such as $w_{\rm suc} = j$. Thus, if $v_j = 0$, $k_j = 0$ holds for $j \in C_2$. In a similar way, we can prove that for any node $i \in \alpha$ $(i \neq 1)$, if $v = (0, 0, \dots, 0)$, then $k_i = 0$. In this way, we have proved that M_1, M_2, …, and M_{N_n} are linearly independent. Therefore, $r(P_{\beta,\alpha}) = N_n - 1 = \frac{q(2q)^n+q-1}{2q-1}$. Inserting this formula into Eq. (21), we can obtain the degeneracy of eigenvalue 0 of P_n, given by Eq. (22).

Appendix C: Explicit expression of eigenvalues of P_n

Notice that all the eigenvalues of P_n lie between -1 and 1. Let λ_n be an eigenvalue of P_n $(n \geq 0)$. Then, one can assume that $\lambda_n = \cos(\theta_n)$ with $0 \leq \theta_n \leq \pi$. Thus, from Eq. (19), we have

$$\cos^2(\theta_n) = \cos^2(\theta_{n-1}/2)\,, \tag{C1}$$

which implies that

$$\cos(\theta_n) = \pm\cos(\theta_{n-1}/2). \tag{C2}$$

Under the constraint of $0 \leq \theta_n \leq \pi$, Eq. (C2) means

$$\theta_n = \theta_{n-1}/2 \quad \text{or} \quad \theta_n = \pi - \theta_{n-1}/2\,, \tag{C3}$$

which enable us to express the eigenvalues for P_n $(n \geq 0)$ in an explicit way as follows.

We use an ordered pair $(\lambda_n, D^{\rm mul}_{\lambda_n})$ to represent an eigenvalue $\lambda_n = \cos\theta_n$ of matrix P_n and its corresponding multiplicity $D^{\rm mul}_{\lambda_n}$. Let Φ_n denote the set of eigenvalues of matrix P_n. Since Φ_n includes eigenvalues -1, 1, 0, and those derived from 0, Φ_n can be classified into $n+1$ non-crossing subsets, denoted by $\Phi_{n,0}$, $\Phi_{n,1}$, $\Phi_{n,2}$, …, $\Phi_{n,n-1}$, and $\Phi_{n,n}$, respectively. $\Phi_{n,0}$ contains eigenvalues -1 and 1 with single degeneracy; $\Phi_{n,1}$ contains all eigenvalues 0; $\Phi_{n,2}$ contains all child eigenvalues directly generated from $\Phi_{n-1,1}$; $\Phi_{n,3}$ contains all child eigenvalues directly generated from $\Phi_{n-1,2}$; and so on. Let $\chi_i = \frac{(q-1)(2q)^{n+1-i}+q}{2q-1}$. Then, Φ_n can be explicitly expressed as follows:

$$\Phi_n = \bigcup_{i=0}^{n} \Phi_{n,i}\,, \tag{C4}$$

where

$$\Phi_{n,0} = \{(\cos 0, 1), (\cos\pi, 1)\} \tag{C5}$$

and

$$\Phi_{n,i} = \bigcup_{k=1}^{2^{i-1}} \left\{\left(\cos\frac{2k-1}{2^i}\pi, \chi_i\right)\right\}\,, \tag{C6}$$

for $1 \leq i \leq n$.

For example, for $n = 3$, we have

$$\Phi_3 = \Phi_{3,0} \bigcup \Phi_{3,1} \bigcup \Phi_{3,2} \bigcup \Phi_{3,3}\,,$$

where

$$\Phi_{3,0} = \{(\cos 0, 1), (\cos\pi, 1)\}\,,$$

$$\Phi_{3,1} = \left\{\left(\cos\frac{\pi}{2}, \frac{(q-1)(2q)^3+q}{2q-1}\right)\right\}\,,$$

$$\Phi_{3,2} = \left\{\left(\cos\frac{\pi}{4}, \frac{(q-1)(2q)^2+q}{2q-1}\right), \left(\cos\frac{3\pi}{4}, \frac{(q-1)(2q)^2+q}{2q-1}\right)\right\}\,,$$

and

$$\Phi_{3,3} = \left\{\left(\cos\frac{\pi}{8}, q\right), \left(\cos\frac{3\pi}{8}, q\right), \left(\cos\frac{5\pi}{8}, q\right), \left(\cos\frac{7\pi}{8}, q\right)\right\}.$$

Appendix D: Number of spanning trees in $H(q, n)$

Let $N_{\rm st}(q, n)$ denote the number of spanning trees in $H(q, n)$. According to the well-known results[48,60], the number of spanning trees, $N_{\rm st}(q, n)$, can be determined by $N_n - 1$ nonzero eigenvalues of the normalized Laplacian matrix for $H(q, n)$, as

$$N_{\rm st}(q, n) = \frac{\prod\limits_{i=1}^{N_n} d_i(n) \prod\limits_{i=2}^{N_n} \sigma_i(n)}{\sum\limits_{i=1}^{N_n} d_i(n)}\,. \tag{D1}$$

Let Θ_n, Δ_n and Λ_n denote $\sum_{i=1}^{N_n} d_i(n)$, $\prod_{i=1}^{N_n} d_i(n)$ and $\prod_{i=2}^{N_n} \sigma_i(n)$, respectively. Then, we have

$$N_{\rm st}(q,n) = \frac{\Delta_n \times \Lambda_n}{\Theta_n} \tag{D2}$$

and

$$N_{\rm st}(q,n-1) = \frac{\Delta_{n-1} \times \Lambda_{n-1}}{\Theta_{n-1}}\,. \tag{D3}$$

We next determine the recursive relation between $N_{\rm st}(q,n)$ and $N_{\rm st}(q,n-1)$. We first determine the recursive relations for Θ_n, Δ_n and Λ_n. It is evident that

$$\Theta_n = \sum_{i=1}^{N_n} d_i(n) = 2E_n = 2(2q)^n = 2q\Theta_{n-1}. \tag{D4}$$

Moreover, according to the obtained results in the main text, it is easy to derive the following recursive relations:

$$\Delta_n = q^{N_{n-1}}\Delta_{n-1} \times 2^{qE_{n-1}} = q^{N_{n-1}} \times 2^{q(2q)^{n-1}}\Delta_{n-1} \tag{D5}$$

and

$$\Lambda_n = \left(\frac{1}{2}\right)^{N_{n-1}-2}\Lambda_{n-1}. \tag{D6}$$

Combining the above-obtained relations, we obtain the recursive relation for $N_{\rm st}(q,n)$ as

$$N_{\rm st}(q,n) = q^{N_{n-1}-1} 2^{q(2q)^{n-1}-N_{n-1}+1} N_{\rm st}(q,n-1)\,. \tag{D7}$$

Using $N_{\rm st}(q,0)=1$, we can now solve Eq. (D7) to obtain the exact expression for the number of spanning trees in $H(q,n)$ as

$$N_{\rm st}(q,n) = 2^{\frac{2q-nq-2q^2+2nq^2-2^{n+1}q^{n+1}+2^{n+1}q^{n+2}}{(2q-1)^2}-n}\, q^{\frac{-q+nq-2nq^2+2^n q^{n+1}}{(2q-1)^2}+n}\,, \tag{D8}$$

which is in complete agreement with that obtained in[59] yet from a different approach, implying that the technique and process of our computation on the eigenvalues and their degeneracies for $H(q,n)$ are correct.
